INTRODUCTION

Malocclusion is demarcated as an occlusion in which there are irregularities in tooth position beyond standard limits, or there is an abnormal relationship. From initial eras of orthodontics, overbite is an essential occlusal characteristic that has been focused for treatment alterations. Improvement of overbite has also been considered to evaluate the excellence of orthodontic treatment results. Deep bite malocclusion is described as “the overlap of upper incisors on the labial surface of lower incisors vertically when the standard limit of 1–2 mm is exceeded”. Deep bite is frequently seen malocclusion in an orthodontic practice and it is the most challenging aberration to treat efficiently. Proffit et al. reported that severe deep bites (overbite ≥5 mm) are seen in approximately 20% of the children and 13% of the adult population, demonstrating around 95.2% of the occlusal deviations in vertical plane. Likewise, the most recent national health and nutrition examination survey (NHANES III) discovered that in US population normal overbite was around 3 mm. Around 14% population presented with an overbite of ≤0 mm and nearly 16% of the population presented with a deep overbite ≥5 mm and demonstrating a frequent occurrence of overbite problems.

A local study conducted in Pakistan on orthodontic patients showed that normal overbite (1–2 mm) was seen in only 16% of their sample, whereas, mild (3–4 mm), moderate (5–6 mm) and severe deep bites (>7 mm) were found in around 28.2%, 20.5% and 30.8% of their sample, respectively. Being a frequently seen disharmony, this is one of the major concerns for an orthodontist. In addition to that, deep bite causing trauma to gingival or palatal tissues is considered as severe problem definitely needing treatment in orthodontic practice.

Incisor over eruption, extreme overjet, malposed canine, molar infra-occlusion, mandibular ramus height, vertical facial type, accentuated curve of Spee, and excessive root torque of the upper incisors labially are features related to the aetiology of deep overbite malocclusion. Faerovig and Zachrisson in their study found that deep bite malocclusion is associated with increased anterior and decreased posterior alveolar basal heights. Furthermore, Zhylich and Suri in their systematic review confirmed that the choice of extraction of
mandibular incisors leads to arch collapse with a resultant bite deepening effect.

Accurate diagnosis and precise appreciation of underlying etiological components will aid the understanding of the condition, prevention, early prediction and eventually in optimal treatment outcomes. Most investigators have described the treatment strategies using anterior bite plane, functional appliances, continuous arch wire mechanics, cervical headgear, utility arches, mini screw implants and orthognathic surgery. Even though there are several approaches available for management of deep bite but the ideal treatment method will be determined by the treatment goals and patient’s characteristics. Nonsurgical treatment substitutes consist extrusion of molars, intrusion of incisors or both in combination. Noroozi demonstrated that extrusion of posterior teeth by every 1 mm reduces the overbite by 1.5 mm anteriorly, confirming that lesser quantities of molar extrusion can cause substantial anterior bite opening. But in deep bite patients with predisposition towards vertical growth pattern, opening bite by extruding posterior segments is not suggested. For these patients true incisor intrusion is an excellent treatment opportunity. In their systematic review verified that extent of intrusion was only 1.9 mm for lower incisors and 1.5 mm for the upper anterior teeth maximally.

Untreated deep bite can cause ulceration of the gingival tissues, attrition of lower incisors, temporomandibular joint disorders and abnormal mandibular function. Therefore, improvement of deep overbite is essential objective of orthodontic therapy. Investigation of underlying aetiological elements is imperative for customized and effective treatment planning. To the best of our understanding, to date dental and skeletal features of deep bite have not been evaluated in Pakistani orthodontic patients. Hence, current study was aimed to determine frequencies of various etiological features and the correlations amongst them.

MATERIAL AND METHODS

This was a cross sectional study design carried out at the Aga Khan University Hospital, Karachi, Pakistan. The time period of present study was from January to December 2014. The present study mainly concentrated on the deep bite malocclusion in patients presenting for the orthodontic treatment. The subjects of Pakistani origin having good quality pre-treatment records, deep bite of greater than 5 mm and fully eruption of permanent 2nd molars were included. Patients with craniofacial anomalies, prior history of orthodontic treatment and clinically missing permanent teeth other than third molars were excluded. A non-probability purposive sampling technique was used.

The data were acquired from pre-treatment dental casts and lateral cephalometric radiographs of the subjects visiting orthodontic clinics from January 2010 to November 2014. Total number of the subjects who were registered during this time period came out to be 656 patients. Deep bite of greater than 5 mm was seen in 141 patients. From this group, 28 patients were excluded because of un-erupted permanent second molars, presence of craniofacial syndromes and clinically missing permanent teeth. Finally the total sample size comprised of 113 subjects.

Cephalometric dental and skeletal measurements and dental cast measurements were used in the study to assess the various skeletal and dental factors of deep bite as shown in figure-1 and table-1. To minimize the chances of error, linear parameters were measured via digital Vernier calliper (0–150 mm ME00183, Dentaurum, Pforzheim, Germany) with reliability of 0.01 mm and an accuracy of 0.02 mm manufacturer’s specification.

SPSS version 19.00, Chicago, Inc. was used for data analyses. Means and standard deviations for age of female and male subjects were determined. Descriptive statistics were used to calculate frequencies as well as the means and standard deviations of various skeletal and dental deep bite etiological factors. All these parameters were correlated using Pearson correlation coefficient. A p-value of <0.05 was taken as statistically significant.

RESULTS

The entire sample comprised of 113 individuals (35 males; 78 females). The female patients were found to have the mean age of 15.7±5 years and the mean age of male patients was 17.2±5 years.

Key outcomes of present cross-sectional study indicate that in individuals with deep bite increased curve of Spee and decreased gonial angle are most frequently seen dental and skeletal factors respectively. Frankfort mandibular plane angle and gonial angle showed the statistically significant strong positive correlation (r=0.66, p=0.000).

Table-2 shows the descriptive statistics of various study parameters of deep bite patients. Table-3 represents the frequencies of skeletal and dental deep bite factors. Increased curve of Spee was most commonly seen factor of dental deep bite (72.6 %), and increased coronal length of lower incisors was least frequent component (5.3%). Diminished gonial angle was most usually seen characteristic of skeletal deep bite (43.4%) and clockwise rotation of maxillary plane was least frequent parameter (26.5%).

Several dental and skeletal deep bite components were correlated by using Pearson
correlation coefficient as shown in table-4. In the correlations amongst skeletal factors, gonial angle was found to have statistically significant negative correlation with ramus/Frankfort horizontal plane \( (r= -0.57, \ p=0.000) \) and positive correlation with mandibular plane angle \( (r=0.66, \ p=0.000) \).

In the correlation between dental factors, statistically significant positive correlation was seen between maxillary and mandibular posterior dentoalveolar heights \( (r=0.35, \ p=0.000) \). Likewise, statistically significant positive correlation was seen amongst maxillary and mandibular anterior dentoalveolar heights \( (r=0.47, \ p=0.000) \). Furthermore, statistically significant positive correlation was also appreciated amongst increased clinical crown lengths of upper and lower incisors \( (r=0.48, \ p=0.000) \).

In the correlations between dental and skeletal parameters, increased lower incisor inclination was observed to have statistically significant negative correlations with mandibular plane angle \( (r= -0.36, \ p=0.000) \) and gonial angle \( (r= - 0.42, \ p=0.000) \).
DISCUSSION

A deep bite malocclusion is a clinical manifestation of various skeletal and dental discrepancies. The inspection of such skeletal and dental factors helps to design efficient mechanics which are crucial for stable deep bite correction.

Ceylan and Eroz evaluated the effect of overbite on mandibular and maxillary morphology. Moreover, Baydas et al. examined the relationship between positions of incisors, overjet, overbite, lower anterior crowding and depth of curve of Spee. The present study targeted at illuminating the numerous skeletal as well as dental factors of deep bite, along with scrutinizing their frequencies and determining the correlations among the investigated factors.

The ramus/Frankfort horizontal angle shows the mandibular ramus angulation with reference to Frankfort horizontal plane. El-Dawlatly et al. in their study on deep bite patients reported the mean value of this angle to be 82.06°±5.54. In our study, the mean value of ramus/Frankfort horizontal angle was found to be 81.53±5.98, which was comparable to their reported value. El-Dawlatly et al. further revealed that reduced gonial angle was most usually seen skeletal factor whereas increased maxillary plane angle was the least common factor, supporting the influence of angulation and growth of mandibular ramus in increasing deep bite compared with maxillary factors. Our results were in agreement to their study in this aspect.

Marshall et al. in their study reported that an accentuated Spee’s curve plays an important role in development of dental deep bite. Similarly, in present study, the increased Spee’s curve also had the greatest influence amongst all the etiological factors. This highlights the significance of levelling Spee’s curve for correction of deep bite by extrusion of lower posterior teeth and intrusion of lower anterior teeth in most deep bite patients.

Second most frequent dental factor was the increased coronal length of upper incisors. Burstone in his study supported intrusion of the upper incisors as the best option for deep bite treatment but, extent of intrusion depends on numerous factors to avoid detrimental effects to the facial appearance. Zachrisson in his study described that the treatment

choice relies on extent of visibility of the upper incisors on smile and at rest; extreme incisor show is best treated with intrusion of the upper front teeth. Extruding posterior teeth or intruding lower front teeth are better treatment options in patients with average or diminished incisor show. The smile arc also guides for designing individualized treatment plan of patients with deep bite malocclusion. For subjects presenting with flat smile arc, intrusion of the upper front teeth is not recommended.

Sancharaearn and Christopher\(^\text{10}\) reported that there is negative correlation amongst inclination of maxillary anterior teeth and the amount of overbite. They established that 6 degrees reduction in inclination leads to 0.3 mm overbite enhancement. In contrast, in our study the retroclination of the upper and lower incisors were the very uncommon factors of deep bite malocclusions. Moreover, inclination of the maxillary incisors and the amount of overbite were not found to have any statistically significant correlation (\(r=-0.18, p=0.057\)).

Upper and lower anterior dentoalveolar heights showed statistically significant medium positive correlation (\(r=0.47, p=0.000\)). In this aspect, our findings were in agreement with those of El-Dawlaty \textit{et al.}\(^\text{55}\) This finding specifies that in individuals in whom upper incisor intrusion is planned for deep overbite improvement, intrusion of lower incisors should be considered and vice versa. This approach can improve stability, avoid excessive intrusion and reduces the risk of root resorption.

In our study increased lower incisor inclination was found to have negative correlation with parameters evaluating the vertical facial growth pattern. This conclusion was in agreement with the Tweed analysis\(^\text{30}\), confirming that as the tendency towards vertical facial growth pattern of increases, the lower incisor inclination tends to decrease and vice versa.

The present study had a limitation. As this study primarily targeted on deep bite components in orthodontic patients, therefore outcomes do not represent the trend of whole Pakistani population. Hence, further research needs to be carried out to measure the etiological deep bite factors on a larger sample on community basis.

CONCLUSIONS

- Reduced gonial angle is the most frequently seen skeletal factor, ratifying the impact of angulation of mandibular ramus and growth in increasing deep bite.
- A deep Spee’s curve is most frequently seen dental parameter, ratifying the significance of intrusion of lower anterior teeth.
- Retroclination of maxillary and mandibular incisors and increased mandibular incisor length were amongst least frequent factors.
